ABSTRACT
Anti microbial photodynamic therapy is one of the most upcoming treatment approaches in field on dentistry. Applications of PDT in dentistry are growing rapidly: the treatment of oral cancer, bacterial and fungal infection therapies, and the photodynamic diagnosis (PDD) of the malignant transformation of oral lesions. Periodontitis as known is polymicrobial disease and this novel therapeutic approach sounds promising in eliminating the microorganisms when used in adjunct to conventional debridement methods. This technique involves application of a photosensitizer and activating it with a light source of specific wavelength. This system in presence of oxygen creates reactive oxygen species that exerts the classic photodynamic reaction. The advantage of this new approach includes rapid bacterial elimination, minimal chance of resistance development and safety of adjacent host tissue and normal microflora. This review discusses about the general principles, mechanism of photodynamic therapy with additional highlights on its application in periodontal diseases.

Keywords: Antimicrobial photodynamic therapy, periodontitis, photosensitizers, lasers.

INTRODUCTION
There have been many changes & developments in dentistry over the past decade than in the previous hundred years combined, and the pace is accelerating! Oral cavity is an abode of variety of microorganisms and periodontitis is an infectious disease caused by number of these organisms. Current treatment techniques involve either periodic mechanical disruption of oral microbial biofilms or maintaining therapeutic concentrations of antimicrobials in the oral cavity, both of which are fraught with limitations. The development of alternative antibacterial therapeutic strategies therefore becomes important in the evolution of methods to control microbial growth in the oral cavity. Numerous adjunct conventional antimicrobial therapies have been attempted. One disadvantage of these therapies is development of resistant strains. So alternate antimicrobial treatment modalities have been researched & one such promising alternative is antimicrobial photodynamic therapy\(^1\).

The history dates back over 3000 years when Indians used psoralens in the treatment of vitiligo & the Egyptians employed it in the treatment of leucoderma.
Later it was rediscovered by Western civilization at the beginning of the twentieth century. In 1834, Kalbrunner isolated the chemical bergapten from bergamot oil but did not use it in any therapeutic application. In 1900, Prime, a French neurologist, used eosin orally in the treatment of epilepsy. He discovered that this induced dermatitis in sun-exposed areas of skin. This discovery then led to the first medical application of an interaction between a fluorescent compound and light.

It was further developed by the Danish physician, Niels Finsen, who at the turn of the last century described the successful treatment of smallpox using red light. He then went on to use ultraviolet light to treat cutaneous tuberculosis and developed the use of carbon arc phototherapy in the treatment of this condition for which he was awarded a Nobel Prize in 1903.

History of photodynamic therapy began when Von Tappeiner, who along with dermatologist Jesionek, used a combination of topical eosin and white light to treat skin tumors. They demonstrated the requirement of oxygen in photosensitization reactions and in 1907 they introduced the term "photodynamic action" to describe this phenomenon. The German physician Friedrich Meyer–Betz performed the first study with what was first called photoradiation therapy (PRT) with porphyrins in humans in 1913. Meyer. In 1989, First Paper on photodynamic therapy was presented at the Congress on photodynamic therapy of Tumours.

This review elucidates the evolution & the current position of photodynamic therapy, its applications in dentistry, especially in periodontal treatments and its likely impact in future.

**COMPONENTS OF PHOTODYNAMIC THERAPY**

Photodynamic reaction is a physico-chemical reaction that basically involves 2 components: Photo sensitizer and the activating light source.

**Photosensitizers**

These are natural or synthetic photoactive compounds that have photosensitizing potential. They function by trapping the light in the form of photons and transferring the energy to other molecules resulting in the liberation of short-lived energetic species that interact with biological systems and produce tissue damage.

Ideal properties of photosensitizers – this includes photo-physical, chemical, and biological characteristics.

- An ideal photosensitizer must be biologically stable.
- Photochemically efficient.
- Selectively retained in the target tissue.
- Low toxicity and fast elimination from the skin and epithelium.
- Absorption peaks in the low-loss transmission window of biological tissues.
- High quantum yield of singlet oxygen production in vivo.
- Cost-effectiveness and commercial availability.
- High solubility in water, injection solutions, and blood substitutes.
- Storage and application light stability.

Generations – Three generations of photosensitizers have evolved over period of time. I generation includes Hematoporphyrins and phthalocyanines. II generation photosensitizers are meso-tetra(hydroxyphenyl)porphyrins marketed as foscan, 5-aminolevulinic acid, tin ethyl etiopurpurin, benzoporphyrin derivative monoacid ring (verteporfin, visudyne) and phenothiazone dyes.
Phenothiazine dyes includes toluidine blue and methylene blue. These are the recent major photosensitizers used in dental field. Both have similar chemical & physiochemical characteristics.

(I). **Toluidine blue** – It’s a blue-violet solution. It stains granules within mast cells, proteoglycans & glycosaminoglycans. Used to detect mucosal tumors or atypical epithelia.

![Toluidine blue](image1)

(2). **Methylene blue** – Redox indicator that is blue in oxidizing environments & becomes colorless on reduction. It is used to identify dysplasia or precancerous lesions of oral mucosa. Recently because of its photocatalytic action it is used for virus inactivations before blood transfusions\(^{16}\). Both dyes are effective against pathogenic bacteria & are hence used extensively in antimicrobial PDT. They are effective against both gram positive & gram negative periopathogens\(^8\).

III generation dyes are modified by targeting with monoclonal antibodies or with non antibody-based protein carriers and protein/receptor systems, and conjugation with a radioactive tag\(^7,32\). These include expanded metallo porphyrins, Metallochlorines, Metallophthalocyanines, Metallononphthalocyanines. Currently, only four photosensitizers are commercially available: Photofrin®, ALA, VisudyneTM (BPD; Verteporfin), and Foscan®. The first three have been approved by the FDA, while all four are in use in Europe.

**Light Sources**

Numerous light sources have been tried ranging from conventional light lamps, lasers to non laser light sources which have evolved recently. Conventionally lasers have been in use for photoactivation\(^{10,32}\). Various lasers that have been used are argon dye lasers, KTP lasers, metal vapor and diode lasers and pumped dye lasers. Most commonly used lasers and wavelengths in intraoral aPDT are Helium-neon lasers – 663 nm, Gallium Aluminum arsenide diode lasers – 630-690 nm, Argon lasers – 488-514 nm. Non laser light sources used are Blue U light systems and light emitting diodes\(^9,10\).

**TECHNIQUES OF ILLUMINATION**

3 basic illumination techniques are practiced that includes superficial, interstitial light delivery and intraoperative PDT\(^3,6\).

**MECHANISM OF ACTION**

The bactericidal effect of photo-dynamic therapy can be explained by two potential, but different, mechanisms. One is DNA
damage and the other is the damage caused to the cytoplasmic membrane of the bacteria by cytotoxic species generated.

The mechanism of action of antimicrobial photodynamic therapy can be briefly described as follows:

After irradiation with light of a specific wavelength (lasers), the photosensitizer at ground state is activated to a highly energized triplet state. The longer lifetime of the triplet state enables the interaction of the excited photosensitizer with the surrounding molecules, and it is generally accepted that the generation of cytotoxic species produced during photodynamic therapy occurs in this state.

The triplet-state photosensitizer follows two different pathways

**Type I Reactions**

Involve hydrogen-atom abstraction or electron-transfer reactions between the excited state of the photosensitizer and an organic substrate molecule of the cells, which produces free radicals and radical ions. These interact with endogenous molecular oxygen to produce highly reactive oxygen species such as superoxide, hydroxyl radicals and hydrogen peroxide, which are harmful to cell membrane integrity, causing irreparable biological damage.

**Type II Reactions**

Involves the production of a highly reactive state of oxygen, known as singlet oxygen ($^1\text{O}_2$), which reacts with the surroundings as a result of its high chemical reactivity. The free radicals and the singlet oxygen convey toxic or lethal effects by damaging the cell membrane and the cell wall.

It seems that the primary cytotoxic agent responsible for the biological effects of the photo-oxidative process is singlet oxygen. Thus, the process of antimicrobial photodynamic therapy is generally mediated by a type II reaction, which is accepted as the major pathway in microbial cell damage.

Microorganisms that are killed by singlet oxygen include viruses, bacteria, protozoa and fungi. Singlet oxygen has a short lifetime in biological systems (<0.04 ls) and a very short radius of action (0.02 lm). The reaction takes place within a limited space, leading to a localized response and making it ideal for application at localized sites without affecting distant molecules, cells or organs.

The process of antimicrobial photodynamic therapy can be visualized as follows:

1. **Activated Photosensitizer**
2. **Photoexcitation**
3. **Triplet State Photosensitizer**
4. **Type I Reactions**
   - Hydrogen-atom abstraction or electron-transfer reactions
5. **Type II Reactions**
   - Production of singlet oxygen
   - Reaction with surroundings
6. **ROS (Reactive Oxygen Species)**
7. **Toxic Effects**
   - Tumor Cells
   - Microorganisms
PHOTOINACTIVATION OF BACTERIAL CELLS
Paul Erlikh in the beginning of 20th century came up with the concept of “magic bullet”. The bullet is considered as a microbe-targeting drug. It reacts only with a germ, not with the host. He hypothesized that the incubation of bacteria with the methylene-blue dye should cause their death at light exposure. In the 1990s, it was observed that there was a fundamental difference in susceptibility to PDT between Gram-positive and Gram-negative bacteria. The photosensitizer molecules bind in a greater extent to cell wall of gram positive cells whereas it binds to a lesser extent only to outer cell wall layer of gram negative cells. The affinity of negatively charged photosensitizers for Gram negative bacteria may be enhanced by linking the sensitizer to a cationic molecule, by the use of membrane-active agents, or by conjugating the sensitizer with a monoclonal antibody that binds to cell-surface-specific antigens. PS does not have to penetrate the bacterium to be effective, or, indeed, even come into contact with the cells. If singlet oxygen can be generated in sufficient quantities near to the bacterial outer membrane, it will be able to diffuse into the cell to inflict damage on vital structures.

PHOTOINACTIVATION OF FUNGI AND VIRUSES
Many studies conducted revealed that lipid-enveloped viruses are more susceptible to PDT than non enveloped strains. Membrane damage and the consequent increased permeability was the proximate cause of cell death after Methylene Blue-mediated PDT on yeast. Human pathogenic parasites have also been killed by combinations of photosensitizers and light.

USE OP PHOTODYNAMIC THERAPY IN PERIODONTICS
The main objective of periodontal therapy is to eliminate deposits of bacteria and bacterial niches by removing the supragingival and subgingival biofilm. It has been demonstrated that conventional mechanical therapy cannot completely remove all periodontal pathogens, as the bacteria invade soft tissues also. Systemic use of antibiotics may be recommended in certain situations as an adjunct to periodontal therapy. But the main disadvantage is increased emergence of antibiotic resistant bacterial strains. Photodynamic therapy is considered as one another novel approach to assist mechanical periodontal therapies in tackling the bacterial challenge. The photosensitizer is placed directly in the periodontal and peri-implant pocket and the liquid agent can easily access the whole root or implant surface before activation by the laser light through placement of the optical fiber directly in the pocket. Photodisinfection of periodontal pocket is carried out in following sequence:
1. Initial mechanical debridement using hand curettes.
2. Photosensitizer is applied via syringe at the diseased site that contains residual bacteria. Occasionally, excess dye solution is removed using water spray.
3. Photosensitization is performed using an intensive light by a special tip applied in the pocket. Singlet oxygen and other very reactive agents that are toxic to bacteria are produced, resulting in photochemical disinfection of the periodontal pocket.

EFFECT OF PDT ON ORAL BIOFILMS
The antimicrobial activity of photosensitizers does not only target bacterial cells but also the oral biofilm.
matrix. It has a direct effect on the polysaccharides on the extracellular matrix on biofilms making the bacterial cells more susceptible to photodamage. Such dual activity is not exhibited by antibiotics. Photodynamic Therapy in Treatment of Periimplantitis

The incidence of peri-implantitis in patients with chronic periodontitis is up to five times greater than in patients who are free of this disease. Treatment of peri-implantitis has become an interesting topic among clinicians and researchers. Conventional mechanical methods such as adjunctive application of systemic or local antibiotics and antiseptics has been generally recommended and are apparently ineffective for complete debridement of the bone defect as well as of the contaminated micro structured implant surface.

Recently lasers and aPDT has gained popularity in treating peri-implant diseases. Numerous studies have shown promising results.
